Abstract

Bacterial endophytes are thought to enter plants either through pre-existing openings in plant tissues or by creating openings by hydrolyzing major plant cell wall components. A lodgepole endophyte, *Paenibacillus polymyxa* P2b-2R, consistently formed endophytic colonies when inoculated in diverse plant hosts, viz., lodgepole pine, western red cedar, corn, canola, and tomato. We were interested to know, whether or not this bacterial strain possesses enzymes that can hydrolyze three major plant cell wall components namely cellulose, xylan, and pectin to facilitate entrance into the host plants. Using a BIOLOG assay, we also tested this bacterial strain's ability to utilize carbon sources that might facilitate its entrance and hence its survival inside host plants. *Paenibacillus polymyxa* P2b-2R hydrolyzed sodium carboxymethylcellulose, beechwood xylan, and sodium polypectate and utilized 39 of the 95 carbon sources (41%) tested. Of the 39 carbon substrates oxidized by P2b-2R, the "carbohydrates" group represents the largest source of utilizable carbon (23 out of 39). Thus, it can be concluded that *P. polymyxa* P2b-2R is able to degrade major cell wall components (cellulose, xylan, and pectin) and utilize some of the available carbon substrates, possibly to gain entry and survive inside the plant and form endophytic colonies thereafter.

Key words: endophyte, *Paenibacillus polymyxa*, colonization, carbon substrate, plant cell wall degradation

Introduction

The term "bacterial endophyte" is used to describe a bacterium that colonizes internal plant tissues without inducing disease symptoms ([Hallmann et al. 1997](#); [Azevedo et al. 2000](#)). Endophytic bacteria are thought to enter plants through pre-existing openings such as emergence sites of lateral roots or wounds to external plant tissues ([James et al. 1994](#)). Alternatively, it is possible that bacterial endophytes may create openings by hydrolyzing major plant cell wall components such as cellulose, hemicellulose, or pectin ([Compant et al. 2005](#); [Reinhold-Hurek et al. 2006](#)). The ability of bacterial endophytes to evade plant defenses is thought to involve the production of enzymes that degrade elicitors of plant immune responses ([Fouts et al. 2008](#)) and to be essential for successful endophytic colonization ([Bulgarelli et al. 2013](#)). By occupying the plant interior, bacterial endophytes may have a comparative advantage over rhizosphere-colonizing bacteria due to ready access to continuous

supplies of nutrients and an additional degree of protection from competition and predation that likely occur outside plant roots (Hallmann et al. 1997). Certain bacterial endophytes may, in turn, enhance the fitness of their plant hosts by inducing systemic defense (Kavino et al. 2007) or providing essential growth-limiting compounds such as nitrogen (N; Dong et al. 1994). *Gluconacetobacter diazotrophicus* was found to possess cellulolytic enzymes (Mateos et al. 1992; Adriano-Anaya et al. 2005) and was able to grow on media supplemented with 10% sucrose and tolerate low pH (Boddey et al. 1991). These characteristics were thought to facilitate endophytic colonization of sugarcane tissues by *G. diazotrophicus*, which was confirmed in studies where it reached high population densities (Döbereiner et al. 1988; Munoz-Rojas and Caballero-Mellado 2003).

Paenibacillus polymyxa is an endospore-forming, non-pathogenic bacterium readily found in environments such as plant roots, soil, and marine sediments (Timmusk et al. 2005; Ravi et al. 2007). Bal et al. (2012) successfully isolated several *Paenibacillus* strains that possess significant acetylene-reduction activity (N-fixing capacity) from the extracts of surface-sterilized lodgepole pine seedling and tree tissues. When one of the strains, *P. polymyxa* P2b-2R, was re-inoculated in lodgepole pine and grown in an N-limited soil for 13 months, the bacterial strain successfully colonized internal stem and root tissues of lodgepole pine seedlings, fixed a significant amount of N from the atmosphere (79%), and promoted the overall growth of seedlings (Anand et al. 2013; Yang et al. 2016). Furthermore, a green fluorescent protein-labeled derivative of P2b-2R was shown to colonize internal tissues of lodgepole pine seedlings (Anand and Chanway 2013a). The ability of *P. polymyxa* P2b-2R to promote growth and to consistently form endophytic colonies inside a broad range of hosts was also confirmed in western red cedar (Anand and Chanway 2013b), corn (Puri et al. 2015, 2016b), canola (Padda et al. 2016b; Puri et al. 2016a), and tomato (Padda et al. 2016a). However, the question arises, how does *P. polymyxa* P2b-2R enter the host plant to form endophytic micro-colonies? In this study, we tested the working hypothesis that *P. polymyxa* P2b-2R possesses enzymes that can hydrolyze major plant cell wall components, like carboxymethylcellulose (CMC), xylan, and sodium polypectate, which then facilitates its entrance into the host plant.

Materials and methods

Paenibacillus polymyxa strain P2b was isolated from surface-sterilized stem tissue of a lodgepole pine seedling that was naturally regenerating near Williams Lake, British Columbia, Canada (latitude: 52°05'N; longitude: 122°54'W; elevation: 1300 m; Sub-Boreal Pine Spruce (SBPSdc) Zone; Bal et al. 2012). *Paenibacillus polymyxa* P2b-2R is a spontaneous antibiotic-resistant mutant that was derived from strain P2b (Bal et al. 2012). *Paenibacillus polymyxa* P2b-2R is resistant to 200 mg/L rifamycin and was stored at −80 °C on combined carbon medium (CCM; Rennie 1981) amended with 20% glycerol (Bal et al. 2012). To evaluate the ability of P2b-2R to degrade plant cell wall components, 50 µL of P2b-2R (~10⁷ cfu/mL) was spot-inoculated on Luria-Bertani (LB) agar amended with one of the following substrates (5 g/L): sodium CMC, beechwood xylan, or sodium polypectate, and incubated for two days at 30 °C. To visualize substrate utilization, plates with sodium CMC or xylan were flooded with 0.5% (w/v) Congo red for 30 min, drained, and then rinsed with 1 mol/L NaCl (Cho et al. 2007). To visualize pectate lyase activity, sodium polypectate plates were flooded with 10% (w/v) copper acetate for 30 min, drained, and rinsed with distilled water (Cho et al. 2007). Clear zones around the bacterial colonies on plates indicated enzyme activity. Carbon substrate utilization of strain P2b-2R was determined using the BIOLOG system (Bochner 1989) according to the protocol recommended by the manufacturer (BIOLOG, Hayward, California, USA). A frozen P2b-2R culture was thawed and subcultured, and a single colony was used to inoculate sterile tryptic soy broth. After 24 h, bacteria were harvested by centrifugation (5000g for 10 min), washed with 0.1 mol/L phosphate-buffered saline (PBS), and resuspended in the same buffer to achieve 28% transmittance at optical density (OD) 640. Aliquots of

P2b-2R-PBS suspension (150 μ L) were pipetted into each microwell of a GP2 plate, incubated at 30 °C for 24 h, and read at OD595 using a plate reader (Spectra Max 340, Sunnyvale, California, USA). Readings above 0.1 at OD595 were considered positive, indicating strong substrate utilization, whereas readings below 0.05 were considered negative, indicating no substrate utilization. Values between 0.05 and 0.1 were considered weakly positive, indicating weak substrate utilization.

Results

All of the plates containing CMC, xylan, or pectin showed visible zones of hydrolysis around colonies after incubating for two days (**Fig. 1**). *Paenibacillus polymyxa* P2b-2R was able to use 41% of the carbon sources on BIOLOG GP2 plates (i.e., 39 of the possible 95 sources; **Table 1**). The bacterial strain readily metabolized arabinose, xylose, mannose, glucose, galactose, and pyruvic acid—biochemicals that constitute major components of plant cell walls. However, it was unable to use other plant cell wall-related compounds such as galacturonic acid, rhamnose, glucuronic acid, and mannan. Carbon sources from the amines/amides, amino acids, polysorbates, nucleotides, or glycerol derivative group were not metabolized by the bacterial strain under these conditions.

Discussion

Bacteria that are capable of endophytic colonization may enter roots passively via existing cracks such as emergence sites of lateral roots (James et al. 1994) or, more actively, by using hydrolytic enzymes to break down plant cell wall components and metabolize organic compounds in the apoplast (Hurek et al. 1994). The latter mode of entry has been reported for plant–microbe interactions ranging from the highly specific symbiosis between *Rhizobium leguminosarum* biovar trifolii and white clover (Mateos et al. 1992) to more casual associations such as those between *Azoarcus* sp. and grasses (Hurek et al. 1994). We examined the capability of *P. polymyxa* P2b-2R to hydrolyze major plant cell wall components like carboxymethylcellulose (CMC), xylan, and sodium polypectate (**Fig. 1**) and to utilize carbon substrates known to comprise typical plant cell walls using in vitro plate assays (**Table 1**). Of the 39 carbon substrates oxidized by P2b-2R, the “carbohydrates” group represented the largest source of utilizable carbon, i.e., 23 of the 39 substrates oxidized (59%; **Table 1**). These carbon sources are found naturally in plants as freely available stored forms such as sucrose, raffinose,

Fig. 1. Major plant cell wall components hydrolyzed by *Paenibacillus polymyxa* P2b-2R. Hydrolysis of (a) cellulose by P2b-2R on Luria-Bertani (LB) agar plates amended with 5 g/L sodium carboxymethylcellulose, followed by flooding with 0.5% (w/v) Congo red; (b) xylan by P2b-2R on LB agar plates amended with 5 g/L beechwood xylan, followed by flooding with 0.5% (w/v) Congo red; and (c) pectin by P2b-2R on LB agar plates amended with 5 g/L sodium polypectate, followed by flooding with 10% (w/v) copper acetate.

and maltose, whereas sugars including arabinose, xylose, mannose, glucose, and galactose exist in association with major components of plant cell walls. Conclusions regarding the relationship between in vitro substrate utilization and the ability to colonize internal tissues of plants cannot be made with certainty; however, our data suggest that P2b-2R could theoretically utilize the aforementioned sugars as well as organic acids such as pyruvic acid for energy generation during endophytic colonization.

It is also interesting to note that P2b-2R was able to hydrolyze sodium polypectate (Fig. 1), the main component of pectin, but was unable to metabolize its main hydrolysis product, D-galacturonic acid. The bacterial strain was unable to use other pectin-related carbon sources as well, including rhamnose and D-glucuronic acid. It is possible that the partial degradation of pectin, known to generate oligogalacturonides (Nothnagel et al. 1983; Aziz et al. 2004), might have triggered a plant innate immune response (Galletti et al. 2009) that eventually limited the endophytic population size of P2b-2R. Alternatively, pectinolytic enzymes may provide enough destabilization of plant cell walls to allow endophytic colonization. By degrading part of the middle lamella, P2b-2R may have better access to organic compounds associated with cellulose and hemicellulose. However, the defense signal pathways in lodgepole pine, as well as the actual products of partial pectin degradation by P2b-2R, need to be identified to evaluate these possibilities.

As the rhizosphere and plant interior represent two vastly different environments (Gottel et al. 2011), it is tempting to speculate that bacteria adapted to different habitats will exhibit distinctly different metabolic profiles. The link between the metabolism of specific carbon substrates and the ability of rhizosphere bacteria to colonize the interior of lodgepole pine seedlings has been reported previously using two strains of *Bacillus polymyxa*, L6-16R and Pw-2R (Shishido et al. 1995). Strain Pw-2R is a root endophyte of lodgepole pine (Shishido et al. 1995) and is capable of metabolizing sorbitol and D-melezitose, a carbohydrate commonly found in conifer sap (Lehninger 1975). As both *P. polymyxa* P2b-2R and *B. polymyxa* Pw-2R are lodgepole pine endophytes, we expected that they would have similar carbon source utilization capabilities, reflecting

their adaptation to colonizing internal tissues of lodgepole pine. However, we found that the use of only eight carbon substrates was common between Pw-2R and P2b-2R when their carbon substrate utilization profiles were compared (Table 2). In addition, D-melezitose and sorbitol, which were readily used by other lodgepole pine endophytes (Shishido et al. 1995, 1999), were not metabolized by P2b-2R. In light of the diversity of available nutrients produced by plants, this small overlap in carbon substrate utilization profiles of P2b-2R and Pw-2R suggests that these two presumably closely related endophytic strains might occupy two distinct nutritional niches of internal tissues of lodgepole pine.

Table 2. Comparison of carbon substrate utilization profiles of *Bacillus polymyxa* Pw-2R and *Paenibacillus polymyxa* P2b-2R.

^aAdapted from [Shishido et al. \(1995\)](#).

To summarize, we found that P2b-2R was able to degrade cellulose, xylan, and sodium polypectate ([Fig. 1](#)), the main constituents of plant cell walls ([Compant et al. 2005](#); [Reinhold-Hurek et al. 2006](#)), which suggests that hydrolytic enzymes are important facilitators of endophytic colonization. However, it is difficult to interpret in vitro substrate hydrolysis without evidence of in situ enzyme activities as plate assays only demonstrate the potential enzyme activities a microbe possesses, which may or may not be expressed in nature. Future experiments involving microscopy and the use of bacterial mutants that lack cellulolytic or pectinolytic enzymes are required to ascertain the importance of in vitro enzyme activities in endophytic colonization by *P. polymyxa* P2b-2R, a microbe which consistently formed endophytic colonies when inoculated in lodgepole pine ([Anand et al. 2013](#); [Yang et al. 2016](#)), western red cedar ([Anand and Chanway 2013b](#)), corn ([Puri et al. 2015, 2016b](#)), canola ([Padda et al. 2016b](#); [Puri et al. 2016a](#)), and tomato ([Padda et al. 2016a](#)).
